## ABSTRACT (maximum 200 words)

Interoperability between software systems is the ability to exchange services from one system to another. In order to exchange services, data and commands are relayed from the service providers to the requesters. Presently, there are some interoperability techniques that aid the exchange of information, ranging from low-level sockets and messaging techniques to more sophisticated middleware technology like object resource brokers. Middleware technology uses higher abstraction than messaging, and can simplify the construction of interoperable applications. It provides a bridge between the service provider and requester by providing standardized mechanisms that handle communication, data exchange and type marshalling. However, in current interoperability techniques, data and services are tightly coupled to a particular server. Furthermore, most developers are trained in developing stand-alone applications rather than distributed applications. This thesis aims at developing a generic interface wrapper that can be used to separate the data and services from the server, and allows the developers to treat distributed data and services as those they are local within an application process space. In addition, the research developed a program to fully automate the process of generating the interface wrapper directly from a specification language such as Prototype System Description Language (PSDL).

## **ABSTRACT**

Interoperability between software systems is the ability to exchange services from one system to another. In order to exchange services, data and commands are relayed from the service providers to the requesters. Presently, there are some interoperability techniques that aid the exchange of information, ranging from low-level sockets and messaging techniques to more sophisticated middleware technology like object resource brokers (CORBA, DCOM). Middleware technology uses higher abstraction than messaging, and can simplify the construction of interoperable applications. It provides a bridge between the service provider and requester by providing standardized mechanisms that handle communication, data exchange and type marshalling. However, in current interoperability techniques, data and services are tightly coupled to a particular server. Furthermore, most developers are trained in developing stand-alone applications rather than distributed applications. This thesis aims at developing a generic interface wrapper that can be used to separate the data and services from the server, and allows the developers to treat distributed data and services as those they are local within an application process space. In addition, the research developed a program to fully automate the process of generating the interface wrapper directly from a

specification language such as Prototype System Description Language (PSDL).

## **I. INTRODUCTION**

### **A. BACKGROUND**

Interoperability between software systems is the ability to exchange services from one system to another. In order to exchange services, data and commands are relayed from the service providers to the requesters. Current business and military systems are typically 2-tier or 3-tier systems involving clients and servers, each running on different machines in the same or different locations. Current approaches for n-tier systems have no standardization of protocol, data representation, invocation techniques etc. Other problems with interoperability are the implementation of distributed systems and the use of services from heterogeneous operating environments. These include issues concerning sharing of information amongst various operating systems, and the necessity for evolution of standards for using data of various types, sizes and byte ordering, in order to make them suitable for interoperation. These problems make interoperable applications difficult to construct and manage.

### **B. CURRENT STATE-OF-THE-ART SOLUTIONS**

Presently, the solutions attempting to address these interoperability problems range from low-level sockets and messaging techniques to more sophisticated middleware

technology like object resource brokers (CORBA, DCOM). Middleware technology uses higher abstraction than messaging, and can simplify the construction of interoperable applications. It provides a bridge between the service provider and requester by providing standardized mechanisms that handle communication, data exchange and type marshalling. The implementation details of the middleware are generally not important to developers building the systems. Instead, developers are concerned with service interface details. This form of information hiding enhances system maintainability by encapsulating the communication mechanisms from the developers and providing a stable interface services for the developers. However, developers still need to perform significant work in incorporating the middleware's services into their systems. Furthermore, they must have a good knowledge of how to deploy the middleware services to fully exploit the features provided.

Current middleware approaches have another major limitation in the design - the data and services are tightly coupled to the servers. Any attempt to parallelize or distribute a computation across several machines therefore encounters complicated issues due to this tight control of the server process on the data.

### **C. MOTIVATION**

Distributed data structures provide an entirely different paradigm. Here, data is no longer coupled to any particular process. Methods and services that work on the data are also uncoupled from any particular process. Processes can now work on different pieces of data at the same time. So far, building distributed data structures together with their requisite interface has proved to be more daunting than other conventional interoperability middleware techniques. The arrival of JavaSpace has changed the scenario to some extent. It allows easy creation and access of distributed objects. However, issues concerning data getting lost in the network, duplicated data items, out-dated data, external exception handling and handshaking of communication between the data owner and data users are still open. The developers have to devise ways to solve those problems and standardize them between applications.

### **D. PROPOSAL**

The situation concerning interoperability would greatly improve if a developer working on some particular application were provided with the features capable of treating distributed objects as local objects within the application. The developers could then modify the distributed object as if it is local within the process. The changes may, however, still need to be reflected on other

applications using that distributed object without creating any problems related to inconsistency. The present thesis aims at attaining this objective by creating a model of an interface wrapper that can be used for a variety of distributed objects. In addition, by automating the process of generating the interface wrapper directly from the interface specification of the requirement, developers' productivity is greatly improved.

The tool, named the Automated Interface Codes Generator (AICG), has been developed to generate the interface wrapper codes for interoperability, from a specification language called the Prototype System Description Language (PSDL) [LUQ88]. The tool uses the principles of distributed data structure and JavaSpace Technology to encapsulate transaction control, synchronization, and notification together with lifetime control to provide an environment that treats distributed objects as if there were local within the concerned applications.

## II. REVIEW OF EXISTING WORKS:

### A. ORB APPROACHES

A basic idea for enhancing interoperability is to make the network transparent to the application developers. The existing approaches [BER99] include 1) Building blocks for interoperability, 2) Architectures for unified, systematic interoperability and 3) Packaging for encapsulating interoperability services. These approaches have been assessed using the Kiviat graphs by Berzins [BER99] with various weight factors. The Kiviat graphs give a good summary of the strong and weak points of various approaches. ORB and Jini are currently the more promising technologies for interoperability.

There are however, some concerns with the ORB models. Sullivan [SUL99] provides a more in-depth analysis of the DCOM model, highlighting the architecture conflicts between Dynamic Interface Negotiation (how a process queries a COM services and interface) and Aggregation (component composition mechanism). The interface negotiation does not function properly within the aggregated boundaries. This problem arises out of the sharing of an interface by the components. An interface is shared if the constructor or QueryInterface functions of several components can return a pointer to it. QueryInterface rules state that a holder of a

shared interface should be able to obtain interfaces of all types appearing on both the inner and outer components. However, an aggregator can refuse to provide interfaces of some types appearing on an inner component by hiding the inner component. Thus, QueryInterface fails to work properly with respect to delegation to the inner interface.

Hence, for the ORB approaches, detailed understanding of the techniques is required to design a truly reliable interoperable system. Programmers however, are trained mostly on standalone programming techniques. Addition of specialized network programming models increases the learning as well as development time, with occasional slippage of target deadlines. Furthermore, bugs in the distributed programs are harder to detect and consequences of failure are more catastrophic. An abnormal program may cause other programs to go astray in a connected distributed environment [LUQ88], [LUQ98].

## **B.    PROTOTYPING**

The demand for large, high quality systems has increased to the point where a quantum change in software technology is needed [LUQ88]. Rapid prototyping is one of the most promising solutions to this problem. Completely automated generation of prototype from a very high-level language is feasible and in-fact generation of skeleton programming structures is very common in the computer world.

One major advantage of the automatic generation of codes is that it frees the developers from the implementation details by executing specification via reusable components [LUQ88].

In this perspective, an integrated software development environment, named Computer Aided Prototyping System (CAPS) has been developed at the Naval Postgraduate School, for rapid prototyping of hard real-time embedded software systems, such as missile guidance systems, space shuttle avionics systems, and military Command, Control, Communication and Intelligence (C3I) systems [LUQ92]. Rapid prototyping uses rapidly constructed prototypes to help both the developers and their customers visualize the proposed system and assess its properties in an iterative process. The heart of CAPS is the Prototype System Description Language (PSDL). It serves as an executable prototyping language at the specification or design level and has special features for real-time system design. Building on the success of computer aided rapid prototyping system (CAPS) [LUQ92], the AICG model also uses the PSDL for the specification and automates the generation of interface codes with the objective of making the network transparent from the developer's point of view.

### **C. TRANSACTION HANDLING**

Building a networked application is quite different from building a stand-alone system in the sense that many

additional issues need to be taken care of for smooth functioning of a networked application. The networked systems are also susceptible to partial failures of computation, which can leave the system in an inconsistent state.

Proper transaction handling is essential to control and maintain concurrency and consistency within the system. Yang [YAN99], examined the limitation of hard-wiring concurrency control (CC) into either the client or the server. He found that the scalability and flexibility of these configurations is greatly limited. Hence, he presented a middleware approach: an external transaction server, which carries out the concurrency control policies in the process of obtaining the data. Advantages of this approach are 1) transaction server can be easily tailored to apply the desired CC policies of specific client applications. 2) The approach does not require any changes to the servers or clients in order to support the standard transaction model. 3) Coordination among the clients that share data but have different CC policies is possible if all of the clients use the same transaction server.

The AICG model uses the same approach, by deploying an external transaction manager provided by SUN in the JINI model [JOY99]. All transactions used by the clients and servers are created and overseen by the manager.

### III. THE BASIC MODEL

#### A. JAVASPACE MODEL

JavaSpace model is a high-level coordination tool for gluing processes together in a distributed environment. It departs from conventional distribution techniques using message passing between processes or invoking methods on remote objects. The technology provides a fundamentally different programming model that views an application as a collection of processes cooperating via the flow of freshly copied objects into and out of one or more spaces. This space-based model of distributed computing has its roots in the Linda coordination language [GEL85] developed by Dr. David Gelernter at Yale University.

A space is a shared, network-accessible repository for objects. Processes use the repository as a persistent object storage and exchange mechanism. As shown in figure 1, processes perform simple operations to write new objects into space, take objects from space, or read (make a copy of) objects in a space. While taking or reading objects, processes use a simple value-matching lookup to find the objects that matter to them. If a matching object is not found immediately, then a process can wait until one arrives. Unlike conventional object stores, processes do not modify objects in the space or invoke their methods

directly. To modify an object, a process must explicitly remove it, update it, and reinsert it into the space. During the period of updating, other processes requesting for the object will wait until the process writes the object back to the space.

Figure 1, JavaSpace operations

#### Key Features of JavaSpace:

- Spaces are persistent: Spaces provide reliable storage for objects. Once stored in the space, an object will remain there until a process explicitly removes it.

- Spaces are transactionally secure: The Space technology provides a transaction model that ensures that an operation on a space is atomic. Transactions are supported for single operations on a single space, as well as multiple operations over one or more spaces.
- Spaces allow exchange of executable content: While in the space, objects are just passive data. However, when we read or take an object from a space, a local copy of the object is created. Like any other local object, we can modify its public fields as well as invoke its methods.

## **B. AICG MODEL**

The interoperability approach underlying the AICG model, proposes a tool for building distributed applications. The tool is designed to generate interface wrappers for data structures or objects that need to be shared, and are particularly useful for applications that can model as flows of objects through one or more servers. Build on top of JavaSpace, the AICG model hides the space and its implementation details entirely from the application. The interface wrapper allows applications to treat distributed data structures or objects as local within the application space. This enhances interoperability by

making the network transparent to the application developers.

The interface wrappers are generated from an extension of a prototype description language called Prototype System Description Language (PSDL).

Some of the salient features of the AICG model are:

- Distributed objects are treated as local objects within the application process. The application codes need not depend on how the object is distributed, since the local object copy is always synchronous with the distributed copy. (Chapter V)
- Synchronization with various applications is automatically handled. Since the AICG model is based on the space transaction secure model, all operations are atomic. Deadlock is prevented automatically within the interface by having only a single distributed copy, and through transaction control. (Chapter VI, XI)
- Any type of object can be shared as long as the object is serializable. Any data structure and object can be distributed as long as it obeys and implements the java serializable feature (Chapter VI, Section B-2).
- Every distributed object has a lifetime. The distributed object lifetime is a period of time

guaranteed by the AICG model for storage and distribution of the object. The time can be set by developer. (Chapter V, Section C)

- All write operations are transaction secure by default. AICG transactions are based on the Atomicity, Consistency, Isolation, and Durability (ACID) properties. (Chapter V, Section D)
- Clients can be informed of changes to the distributed object through the AICG event model. A client application can subscribe for change notification, and when the distributed object is modified, a separate thread is spawned to execute the callback method defined by the developer. (Chapter V, Section E)
- The wrapper codes are generated from high-level descriptive languages; hence, they are more manageable and more maintainable.

THIS PAGE IS INTENTIONALLY LEFT BLANK

#### IV. DEVELOPING DISTRIBUTED APPLICATIONS WITH THE AICG TOOL

This section describes the steps for developing distributed applications using the AICG model. An example of a C4ISR application is introduced in section 4.1.2 to aid the explanation of the process. The same example will be used throughout this paper.

##### A. DEVELOPMENT PROCEDURES

The developer starts the development process by defining shared objects using the Prototype System Description Language (PSDL). The PSDL is processed through a code generator (PSDLtoSpace) to produce a set of interface wrapper codes (figure 2). The interface wrapper contains the necessary codes for interaction between the applications and the space without the need for the developers to be concerned with the writing and removing of objects in the space. The developers can treat shared or distributed objects as local objects, where synchronization and distribution is automatically handled by the interface codes.

Figure 2, PSDL to Space

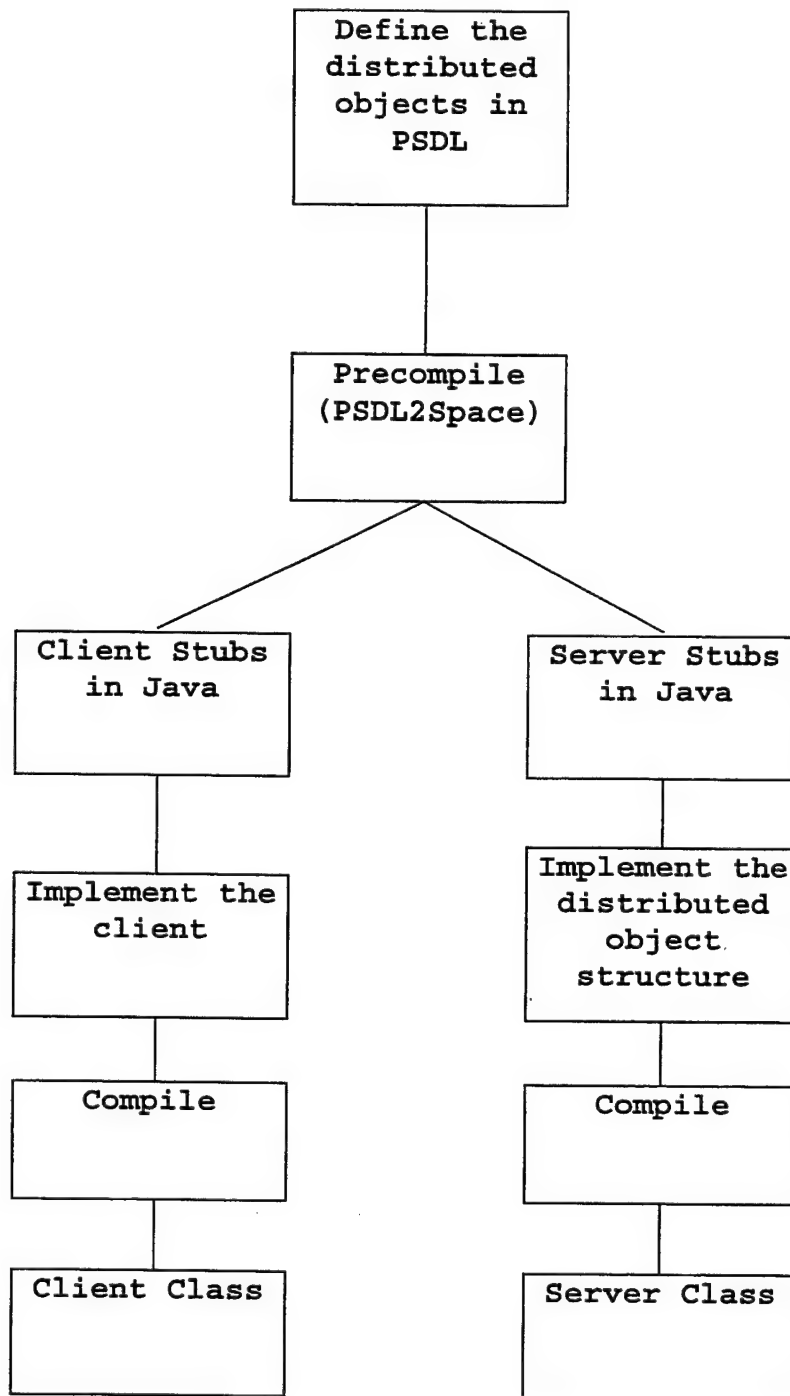

Figure 3, Generating the interface codes

The complete cycle for generating the interface codes is shown in figure 3.

#### **B. INPUT DEFINITION TO THE CODE GENERATOR**

The following example demonstrates the development of one of the many distributed objects in the C4ISR system. Airplane positions picked up from the sensors are processed to produce track objects. These objects are distributed over a large network and used by several clients' stations for displaying the positions of planes. Each track or plane is identified by track number. The tracks are 'owned' by a group of track servers, and only the track servers can update the track positions and its attributes. The clients only have read access on the track data. Figure 4 shows the PSDL codes for the track object and its methods. Figure 5 shows the PSDL codes for the **Track\_list** object and its methods.

The PSDL grammar used for the AICG is an extended version of the original PSDL grammar (Appendix A). PSDL model is very extensive and can be used to model an entire distributed system. However, the AICG only used a portion of the PSDL to describe the interface between systems. In another word, interactions between applications are defined using the PSDL but not the application itself. Because of this, slight modifications on the PSDL grammar were needed.

The complete listing of the changes in the grammar statements can also be found in Appendix A.

The track PSDL starts with the definition of a type called **track**. It has only one identification field **tracknumber**. Of course, the **track** objects can have more than one field, but only one field is in this case is used to uniquely identify any particular **track** object. The type **track\_list** shown in figure 5, on the other hand, does not need an identification field since there is only one **track\_list** object in the whole system. **Track\_list** is used to keep a list of all the active tracks **tracknumber** in the system at that moment in time.

All the operators (methods) of the type are defined immediately after the specification. Each method has a list of *input* and *output* parameters that define the arguments of the method. The most important portion in the method declaration is the *implementation*. The developer must be able to define the type of operation the method is supposed to perform. The operations are *constructor* (used to initialize the class), *read* (no modification to any field in the class) and *write* (modification is done to one or more fields in the class). These are necessary, as the code generated will encapsulate the synchronization of the distributed objects.

<pre> Type track SPECIFICATION   tracknumber: integer END  OPERATOR track SPECIFICATION   INPUT x:integer END IMPLEMENTATION   SPACE   PROPERTY SPACEMODE=     CONSTRUCTOR   END END  OPERATOR getID SPECIFICATION   OUTPUT x:integer END IMPLEMENTATION   SPACE   PROPERTY SPACEMODE= READ   END END  OPERATOR setCallsign SPECIFICATION   INPUT sign: string END IMPLEMENTATION   SPACE   PROPERTY SPACEMODE= WRITE   PROPERTY TRANSACTIONTIME =     300   END END  OPERATOR getCallsign SPECIFICATION   OUTPUT sign: string END IMPLEMENTATION   SPACE   PROPERTY SPACEMODE= READ   END END </pre>	<pre> OPERATOR setPosition SPECIFICATION   INPUT post : position_type END  IMPLEMENTATION   SPACE   PROPERTY SPACEMODE = WRITE   PROPERTY TRANSACTIONTIME =     2000   END END  OPERATOR getPosition SPECIFICATION   OUTPUT post : position_type END IMPLEMENTATION   SPACE   PROPERTY SPACEMODE = READ   END END  IMPLEMENTATION   SPACE   PROPERTY SPACENAME= DODSpaces   PROPERTY OWNERSHIP = YES   PROPERTY SECURITY = SERVER   PROPERTY LEASE = 12000   PROPERTY CLONE = MANY   PROPERTY NOTIFY = NO   PROPERTY RETRY = 10 END </pre>
---	--

Figure 4, Track example in PSDL

<pre> TYPE track_list SPECIFICATIO END  OPERATOR track_list SPECIFICATION END IMPLEMENTATION SPACE PROPERTY SPACEMODE= CONSTRUCTOR END END  OPERATOR getID SPECIFICATION INPUT index: integer OUTPUT x:integer END IMPLEMENTATION SPACE PROPERTY SPACEMODE= READ  END END  OPERATOR setNewID SPECIFICATION INPUT id: integer END IMPLEMENTATION SPACE PROPERTY SPACEMODE= WRITE END END  OPERATOR removeID SPECIFICATION INPUT id: integer END IMPLEMENTATION SPACE PROPERTY SPACEMODE= WRITE PROPERTY TRANSACTIONTIME = 2000 END END END </pre>	<pre> IMPLEMENTATION SPACE PROPERTY SPACENAME= DODSpaces PROPERTY OWNERSHIP = YES PROPERTY SECURITY = SERVER PROPERTY LEASE = 0 PROPERTY CLONE = ONE PROPERTY NOTIFY = YES PROPERTY RETRY = 5 END  TYPE position_type SPECIFICATION END IMPLEMENTATION JAVA position.java END </pre>
--	--

Figure 5, Track list example PSDL

The other field in the implementation portion of the method, is *transactiontime*. *transactiontime* defines the upper limit in milliseconds within which the operation must be completed. The transaction property is discussed in detail in Chapter VI, Section D. Method Implementation property fields include:

```
SPACEMODE = CONSTRUCTOR/ : Type of operation
                        READ /WRITE
TRANSACTIONTIME = 999    : Upper limit of the operation
                        : in ms.
                        : Transaction is disabled by
                        : setting the value to 0.
```

At the end of each class is the implementation section. This section is the class-wide attributes of the ACIG properties. The explanation of the attributes is:

```
SPACENAME= DODSpaces      : Which Java Space to be used
OWNERSHIP = YES/NO        : Every object has at most one
                        : owner?
SECURITY = SERVER         : Only Server application can
                        : modify the object
                        /Client : All application can modify
                        : the object
```

LEASE = 999	: Object life time in ms. For
	: lease that last forever, set
	: it to 0
CLONE = ONE	: There is only one object of
	: this type
	: in the space at a time
/MANY	: There can be many object of
	: the this type in the space
	: simultaneously.
NOTIFY = YES	: Notification of changes
	: allowed.
/NO	: Notification of changes not
	: allowed.
RETRY = n	: Retry all communication
	: operations on the space for
	: n times, before raising an
	: exception.

### C. RUNNING THE PSDL2SPACE PROGRAM

Each distributed class in the PSDL will generate a set of interface wrapper files after executing the PSDL2Space program.

The command line for PSDL2Space is:

- PSDL2Space <destination dir> <data dir> <psdl file>

Figure 6 below shows the files created for executing the command:

```
C:> PSDL2Space interfaceAICG aicgDir track.psd1
```

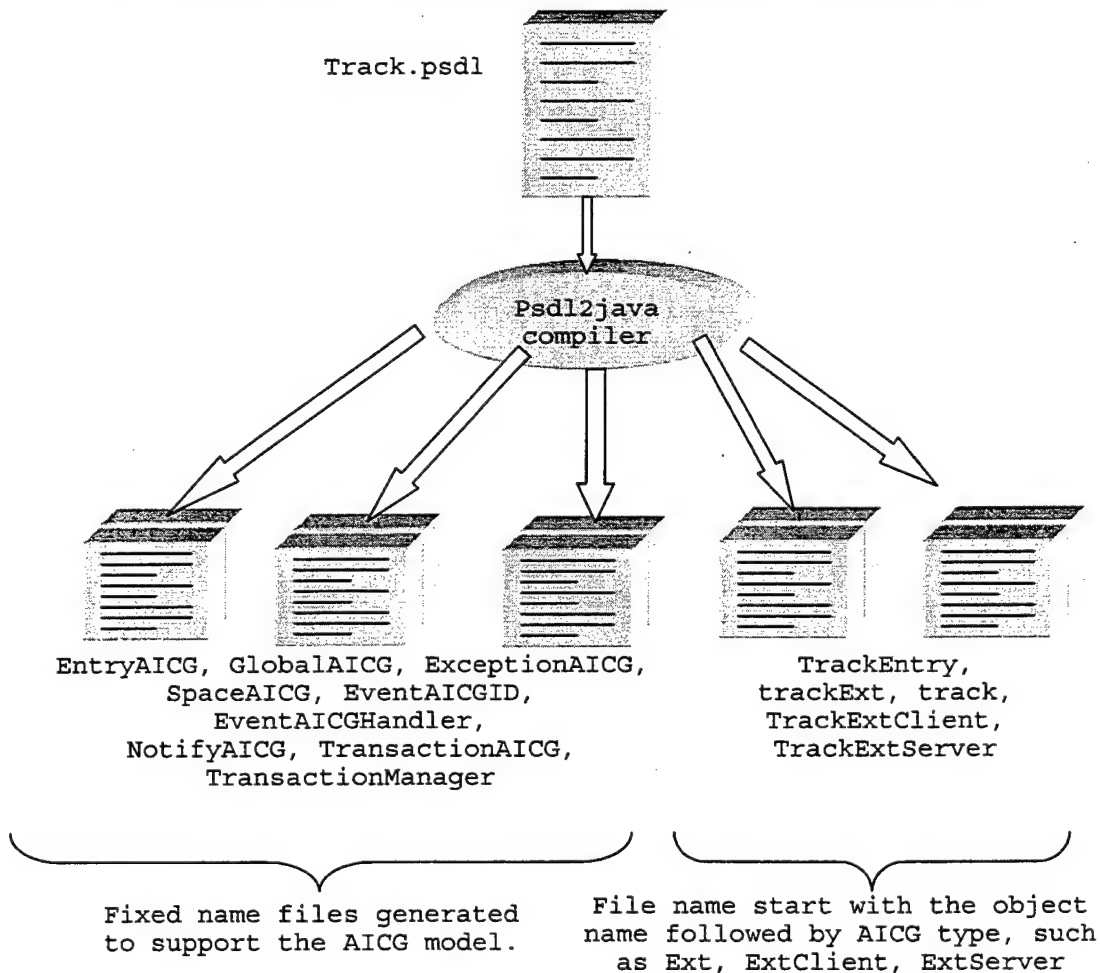

Figure 6, AICG generated

Most of the generated files can be ignored except the following:

- I. `Track.java`: this file contains the skeleton of the fields and the methods of the track class. The user is supposed to fill the body of the methods.
- II. `TrackExtClient.java`: this is the wrapper class that the client initialized and used instead of the track class.
- III. `TrackExtServer.java`: this is the wrapper class that the server initialized and used in replace for the track class.
- IV. `NotifyAICG.java` : this class must be extended or implemented by the application if event-notification and call-back are needed.

The methods found in the `trackExtClient` and `trackExtServer` have the same method names and signatures of the track class. In fact, the track class methods are been called within `trackExtClient` or `trackExtServer`.

#### **D. THE SERVER SIDE OF TRACK**

Every AICG server must have a main program that initializes the AICG environment and creates the distributed objects. An example of a small portion of the server program

is given below. The full example listing can be found in Appendix B. It is noted that the once the distributed object is instantiated, it behaves like any local object that be invoked or modified.

```
public class TrackServer implements Runnable
{

    public void run(){
        // TODO: Add initialization code here
        trackExtServer trk[];
        position_type pos;

        try{
            // Start the transaction manager
            trackExt.trackStartTxn();
            // create array of for 10 tracks
            trk = new trackExtServer[10];

            rd = new Random();
            // create 10 tracks with random position
            for (int i=0; i <10; i++){
                // create the tracks
                trk[i] = new trackExtServer(i);
                // generate a random number
                pos = new position_type
                    (rd.nextInt(),rd.nextInt());
                // set the position
                trk[i].setPosition(pos);
            }
        }catch (Exception e){
            System.err.println("Exception");
            e.printStackTrace();
        }
    }
}
```

Figure 6, An example of Track Server

#### E. THE CLIENT SIDE OF TRACK WITHOUT EVENT-NOTIFICATION ENABLED

The client program example consists of a single Java class, TrackClient. This class provides the main method that performs only one main task; Initialize the trackExtClient object. Of course, the client must know the track number in advance before it can locate the distributed object. Since event-notification is not enabled, the client has to keep polling on the contents of the track. Part of TrackClient is shown below in figure 8. The full listing of TrackClient is found in Appendix B.

```
public class TrackClient implements Runnable
{
    public void run(){
        // initialize and search for the track in the space
        try{
            trk = new trackExtClient[10];
            //initialize the track clients
            for (int i=0; i <10; i++){
                trk[i] = new trackExtClient(i);
            }
            // loop every 6 seconds
            while (true){
                Thread.sleep(6000);
                for (int i =0; i <10; i++){
                    System.out.print("ID :" + trk[i].getID());
                    System.out.println(" X :" +
                        trk[i].getPosition());
                }
            }
        }catch (Exception e){
            System.err.println("Exception");
            e.printStackTrace();
        }
    }
}
```

Figure 8, Example of Track Client without Notification

#### F. THE CLIENT SIDE OF TRACK WITH EVENT-NOTIFICATION ENABLED

The client program is the same as the one above with the only exception is that the notification is enabled. Hence, whenever the server changes the contents of the track object, listenerAICGEvents method will be invoked.

```
public class TrackClient implements Runnable, notifyAICG
{
    public void run(){
        try{
            // initialize event notification
            handler = new eventAICGHandler(this);
        }catch (exceptionAICG e){
        }
        try{
            trk = new trackExtClient[10];
            // enable this track with notification for changes
            trk[i].setEvent(handler);
        }
    }
    // listenerAICGEvent will be invoked when changes occur
    public void listenerAICGEvents(Object obj){
        try {
            trackExtClient trkClient = (trackExtClient) obj;
            System.out.println("Notified detected");
            System.out.print("ID :" + trkClient.getID());
            System.out.println("Posit" + trkClient.
                getPosition());
        }catch (Exception e){
            System.err.println("Exception");
        }
    }
}
```

## V. CHARACTERISTICS OF AICG MODEL

### A. DISTRIBUTED DATA STRUCTURE AND LOOSELY COUPLED PROGRAMMING

Conceptually a distributed data structure is one that can be accessed and manipulated by multiple processes at the same time without any consideration for any machine physically executing those processes. In most distributed computing models, distributed data structures are hard to achieve. Message passing and remote method invocation systems provide a good example of the difficulty. Most of the systems tend to keep data structure behind one central manager process, and processes that want to perform work on the data structure must "wait in line" to ask the manager process to access or alter a piece of data on their behalf. Attempts to parallelize or distribute a computation across more than one machine face bottlenecks since data are tightly coupled by the one manager process. True concurrent access is rarely achievable.

Distributed data structures provide an entirely different approach where we uncouple the data from any particular process. Instead of hiding data structure behind a manager process, we represent data structures as collections of objects that can be independently and

concurrently accessed and altered by remote processes. Distributed data structures allow processes to work on the data without having to wait in line if there are no serialization issues.

The distributed protocol for modification ensures synchronization by enforcing that a process wishing to modify the object has to physically remove it from the space, alter it and write it back to the space. There can be no way for more than one process to modify an object at the same time. However, this does not prevent other processes from overwriting the corrected data. For example, in the normal JavaSpace, process A instead of performing a "take" follow by a "write operation, the programmer wrote a "read" operation, followed by a "write" operation. This results in 2 copies of the object in the Space. The AICG model prevents this by encapsulating the 3 basic commands from the developers. All modification on the object are automatically translated to "take", followed by "write" and all operations that access the fields of the distributed object are translated to "read". These ensure that local data are up-to-date and serialization is maintained (figure 10).

### Creating a Distributed Object

### Reading a field of a distributed object

### Updating a distributed object

Figure 10, Interaction between Space through AIGC Interface

Loosely-coupled programming also has its own limitations. Distributed objects may be lost if a process removes it from the space and subsequently crashes or is cut off from the network. Similarly, the system may enter a deadlock state if processes request more than one distributed object while, at the same time, holding on to distributed objects required by other processes. In cases like this, the AICG model groups multiple operations into a transaction to ensure that either all operations are completed or none occurs, thereby maintaining the integrity of the application. Hence, deadlock is prevented through transaction control. The application can retry the operation immediately or wait for a random time before performing the operation again.

#### **B. SYNCHRONIZATION**

Synchronization plays a crucial role in any design of distributed application. Inevitably, processes in a distributed system need to coordinate with one another and avoid bringing the system into an unstable state such as deadlock. Creating distributed applications with AICG can significantly ease the burden of process synchronization since synchronization is already built into the AICG operations. Multiple processes can read an object in a space

at any time, but when a process wants to update an object, it has to remove it from the space and thereby gain exclusive access to it first. Hence, coordinated access to objects is enforced by the AICG interface doing *read*, *take* and *write* operations.

More advanced and complex synchronization schemes can be easily build upon from the basic atomic features of the AIGC operations. An example is semaphores. Semaphores, a synchronization construct that was first used to solve concurrency problems in operating systems, are commonly found in multithreaded programming languages, but are more difficult to achieve in distributed systems. Semaphores are typically implemented as integer counters that require special language or hardware support to ensure the atomic properties of the *UP* (signal) and *DOWN* (wait) operations. Using AIGC space model, we could easily implement a semaphore as a shared variable that holds an integer counter. By assigning a distributed variable or object as a semaphore, groups of distributed objects can be synchronized. Hence, the AIGC model permits the developers to develop more complicated distributed applications without being concerned about synchronization and deadlock. Furthermore, all operations within the AIGC model can impose transaction control with timeout monitoring. After the

timeout period, the transaction would rollback the application to a stable state.

### C. OBJECT LIFE TIME (LEASES/TIMEOUT)

Leasing provides a methodology for controlling the life span of the distributed objects in the AICG space. This allows resources to be freed after a fixed period. This model is beneficial in the distributed environment, where partial failure can cause holders of resources to fail thereby disconnecting them from the resources before they can explicitly free them. In the absence of a leasing model, resources could grow without bound.

There are other constructive ways to harness the benefit of the leasing model besides using it as a garbage collector. As for example, in a real-time system, the value of the information regarding some distributed objects becomes useless after certain deadlines. Accessing obsolete information can be more damaging in this case. By setting the lease on the distributed object, the AICG model automatically removes the object once the lease expires or the deadline is reached.

JavaSpaces allocate resources that are tied to leases. When a distributed object is written into a space, it is granted a lease that specifies a period for which the space

guarantees its storage. The holder of the lease may renew or cancel the lease before it expires. If the leaseholder does neither, the lease simply expires, and the space removes the entry from its store.

The AICG model simplified the JavaSpace lease model into two configurations. These are:

- I. Generally, the distributed object lasts forever as long as the space exists, even if the leaseholder (the process that creates the object) has died. This configuration is enabled by setting the *SPACE* lease property in the Implementation to 0.
- II. In the real-time environment, the distributed object lasts for a fixed duration of *x* ms specified by the object designer. To keep the object alive, a write operation must be performed on the object before the lease expires. This configuration is set through the *SPACE* lease property in the Implementation to the time in ms required.

Hence, the developer must provide due consideration towards leasing while developing the application. If an object has a lifetime, it must be renewed before it expires. In the AICG model, renewal is done by calling any method

that modifies the object. If no modification is required, the developer can consider defining a dummy method with the spacemode set to "write". Invoking that method will automatically renew the lease.

#### **D. TRANSACTIONS**

The AICG model uses the Jini Transaction model, which provides generic services concerning transaction processing in distributed computing environment.

##### **1. Jini Transaction Model**

All transactions are overseen by a transaction manager. When a distributed application needs operations to occur in a transaction secure manner, the process asks the transaction manager to create a transaction. Once a transaction has been created, one or more processes can perform operations under the transaction. A transaction can complete in two ways. If a transaction commits successfully, then all operations performed under it are complete. However, if problems arise, then the transaction is aborted and none of the operations occurs. These semantics are provided by a two-phase commit protocol that is performed by the transaction manager as it interacts with the transaction participants.

## 2. AICG Transaction Model

AICG model encapsulates and manages the transaction procedures. All operations on the distributed object can be either with transaction control or without. Transaction control operations are controlled with a default lease of 2 seconds. This default value of leasing time may, however, be changed by the user. The transaction lease is kept by the transaction manager as part of the leased resource, and when the lease expires before the operation being committed, the transaction manager aborts the transaction.

The AICG model by default, enables all transaction for write operations and the transaction lease time is two seconds. The developer can modify the lease time through the PSDL SPACE *transactiontime* property.

```
PROPERTY transactiontime = 0 : Disable transaction for  
                             that method  
/n : Set the lease time to n  
      milliseconds.
```

No read operations in the AICG model have the transaction enable. However, the user can enable it by using the property *transactiontime* with the upper limit in transaction time for the read operation.

## **E. AICG EVENT NOTIFICATION**

In the distributed and loosely-coupled programming environment, it is desirable for an application to react to changes or arrival of newly distributed objects instead of "busy waiting" for it through polling. AICG provides this feature by introducing a callback mechanism that invokes user-defined methods when certain conditions are met.

Java provides a simple but powerful event model based on event sources, event listeners and event objects. An event source is any object that "fires" an event, usually based on some internal state change in the object. In this case, writing an object into space would generate an event. An event listener is an object that listens for events fired by an event source. Typically, an event source provides a method whereby listeners can request to be added to a list of listeners. Whenever an event source fires an event, it notifies each of its registered listeners by calling a method on the listener object and passing it an event object.

Within a Java Virtual machine (JVM), an application is guaranteed not to miss an event fired from within. Distributed events on the other hand, had to travel either, from one JVM to another JVM within a machine or between machines networked together. Events traveling from one JVM

to another may be lost in transit, or may never reach their event listener. Likewise, an event may reach its listener more than once.

Space-based distributed events are built on top of the Jini Distributed Event model, and the AICG event model further extends it. When using the AICG event model, the space is an event source that fires events when entries are written into the space matching a certain template an application is interested in. When the event fires, the space sends a remote event object to the listener. The event listener codes are found in one of the generated AICG interface wrapper files. Upon receiving an event, the listener would spawn a new thread to process the event and invoke the application callback method. This allows the application codes to be executed without involving the developer in the process of event-management.

There are a few steps for setting up AICG event for a particular application. Firstly, the distributed objects must have the SPACE properties for *Notification* set to yes. One of the application classes must *implement* (java term for inherit) the *notifyAICG* abstract class. The *notifyAICG* class has only one method, which is the callback method. The user class must override this method with the codes that need to be executed when an event fires. More details on the

implementation of the notifyAICGHandler have been included in the next chapter.

## VI. AICG DESIGN

This section explains the design of the AICG and the codes that are generated from `psdl2java` program. The interface wrapper codes examples used in this section are generated from the track PSDL of figure 4.

### A. AICG ARCHITECTURE

The AICG architecture consists of four main modules: Interface modules, Event modules, Transaction modules and the Exception module. The interface modules implement the distributed object methods and communicate directly with the application. In reference to the example, the interface modules for the `track.psd1` are `entryAICG`, `track`, `trackExt`, `trackExtClient`, `trackExtServer`. Instead of creating the actual object (`track`), the application should instantiate the interface class either the `trackExtClient` or `trackExtServer`. Event modules (`eventAICGID`, `evenAICGHandler`, `notifyAICG`) handle external events generated from the JavaSpace that are of interest to the application. Transaction modules (`transactionAICG`, `transactionManagerAICG`) support the interface module with transaction services. Lastly, the exception module (`exceptionAICG`) defines the possible types of exceptions

that can be raised and need to be handled by the application. Figure 11 shows the architecture of the generated interface wrapper and the interaction with the other modules and the application.

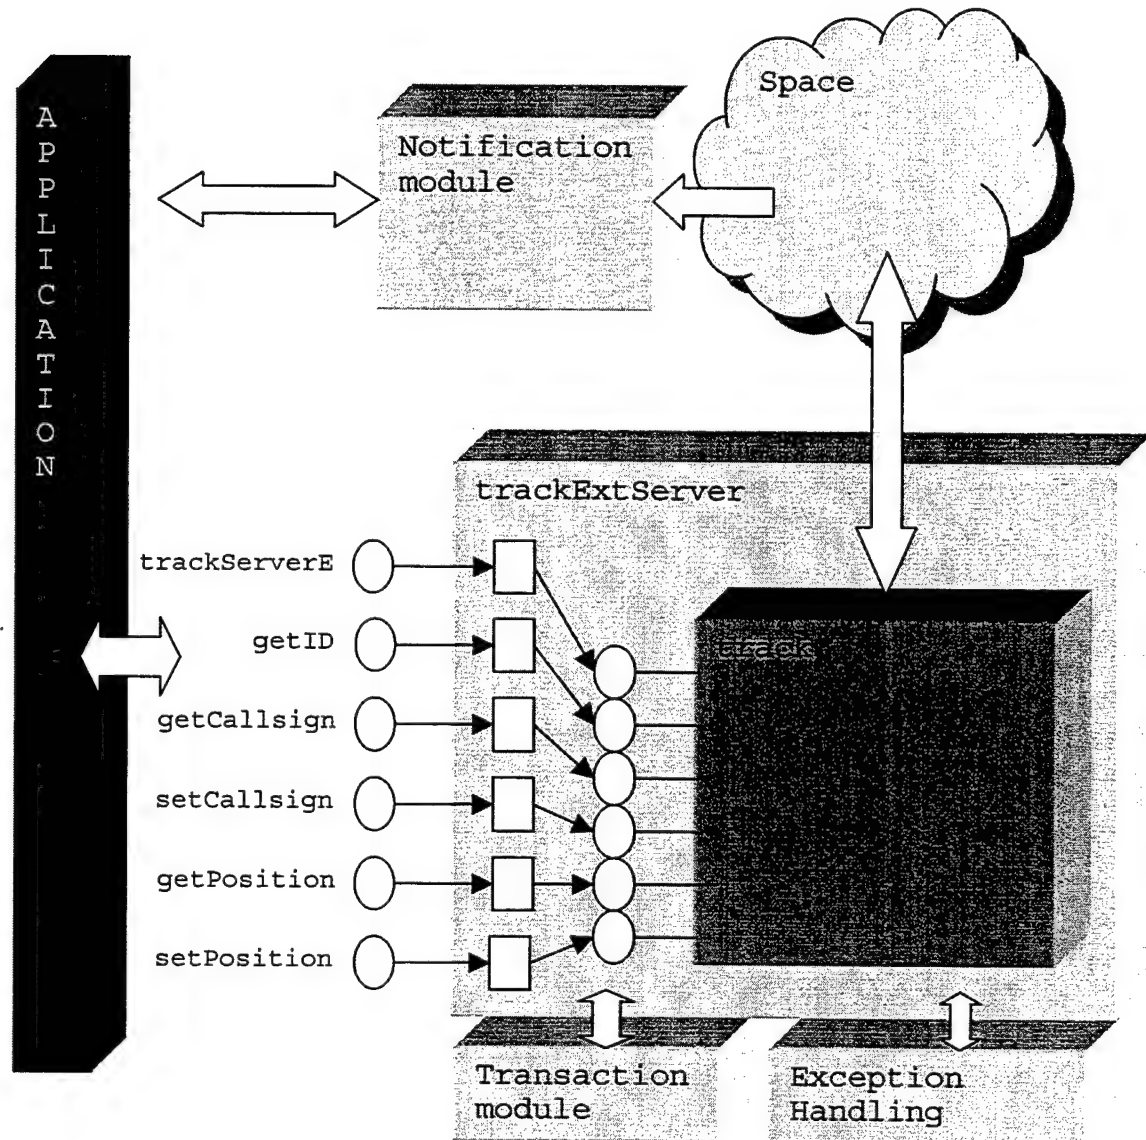

Figure 11, Architecture of the generated interface wrapper and the interaction with the other modules and application

Each time the application instantiate a track class by creating a new trackExtServer, the following events take place in the Interface:

1. An Entry object is created together with the track object by the trackExtServer. The tack object is placed into the Entry object and stored in the space.
2. Transaction Manager is enabled.
3. The reference pointer to trackExtServer is returned to the application.

Each time a method (getID, getCallsign, getPosition) that does not modify the contents of the object is invoked, the following events take place in the Interface:

1. When the application invokes the method through the Interface (trackExtServer/trackExtClient).
2. The Interface performs a Space "get" operation to update the local copy.
3. The method is then executed on the updated copy of the object to return the value back to the application.

Each time a method (`setCallsign`, `setPosition`), which does modify the contents of the object is invoked, the following events take place in the Interface:

1. The application invokes the method through the Interface.
2. The interface performs a Space "take" operation, which retrieves the object from the space.
3. The actual object method is then invoked to perform the modification.
4. Upon completion of the modification, the object is returned to the space by the interface using a "write" operation.

#### **B. INTERFACE MODULES**

The interface modules consist of the following modules; an entry (`entryAICG`) that are stored in space, the actual object (`track`) that are shared and the object wrapper (`trackExt`, `trackExtClient`, `trackExtServe`).

##### **1. Entry**

A space stores *entries*. An entry is a collection of typed objects that implements the Entry interface. The base class of the AICG distributed object is shown in figure 11.

```

public abstract class entryAICG implements Entry
{
    // main identification number
    public Integer entryID;

    // required by JavaSpace default constructor
    public entryAICG( ) {
    }

    public entryAICG(int id){
        entryID = new Integer(id);
    }

    // return the object stored in the entry
    public abstract Object getObject( );
}

```

Figure 12, An example of entryAICG class

The Entry interface is empty; it has no methods that have to be implemented. Empty interfaces are often referred to as "marker" interfaces because they are used to mark a class as suitable for some role. That is exactly what the Entry interface is used for, to mark a class appropriate for use within a space.

All entries in the AICG extend from this base class. It has one main public attribute, an identifier and an abstract method that returns the object. Any type of object can be stored in the entry. The only limitation is that the object must be serializable. Serializability allows the java virtual machine to pass the entire object by value instead of by reference. Here is an example "track" entry codes generated by the AICG from the PSDL file in figure 4. The

interface contains the object track in one of the field and an ID.

```
public abstract class trackEntry extends entryAICG
{
    // ID is required if there are more than one similar object in
    // the space
    public Integer aicgID1;

    // track object
    public track data;

    // default Constructor
    public trackEntry(){ }

    // Constructor with information extracted from the track PSDL
    // file.
    public trackEntry(int aid, Integer aicgID1, track inData){
        super(aid);
        data = inData;
        this.aicgID1 = aicgID1;
    }
    public Object getObject(){
        return data;
    }
}
```

Figure 13, An example of Entry class

All Entry attributes are declared as publicly accessible. Although it is not typical of fields to be defined in public in object-oriented programming style, the associative lookup is the way the space-based programs locate entries in the space. To locate an object in space, a template is specified that matches the contents of the fields. By declaring entry fields public, it allows the space to compare and locate the object. AICG encourage

object-oriented programming style by encapsulating the actual data object into the entry. The object attributes can then be declared as private and made accessible only through clearly defined public methods of the object.

## 2. Serialization

Each distributed interface object is a local object that acts as a proxy to the remote space object. It is not a reference to a remote object but instead a connection passes all operations and value through the proxy to the remote space. All the objects must be serializable in order to meet this objective. The Serializable interface is "marker" interface that contains no methods and serves only to mark a class as appropriate for serialization. The Serializable interface is shown in figure 14 together with the example of track class implementing the interface.

```
public abstract interface Serializable {  
    // this interface is empty  
}  
  
// An example of the track class implementing the interface  
//Serializable  
public class track implements Serializable {  
    // since Serializable is a marker interface  
    // no methods need to be override.  
}
```

Figure 14, Serializable interface class

### 3. The Actual Distributed Object

We now look at the actual objects that are shared between the servers and clients. The PSDL2Space generates a skeleton version of the actual class with the methods names and its arguments. The body of the methods and its fields need to be filled by the developers. The track class generated is shown in figure 15. The track class with the body and fields added is listed in Appendix B.

```
public class track implements java.io.Serializable
{
    private Integer trackNumber;

    public track(int inID){
        // insert the body here
    }
    public int getID(){
        // insert the body here
    }

    public void setPosition(position_type post){
        // insert the body here
    }

    public position_type getPosition(){
        // insert the body here
    }

    public String getCallsign(){
        // insert the body here
    }

    public void setCallsign(String sign){
        // insert the body here
    }

    // automatically generated do not delete!!
    public Integer autoGetID1(){
        return trackNumber ;
    }
}
```

Figure 15, An example of a distributed class generated by PSDL2Space

#### 4. Object Wrapper

Wrapping is an approach to protecting legacy software systems and commercial off-the-shelf (COTS) software products that require no modification of those products [BER99]. It consists of two parts, an adapter that provides some additional functionality for an application program at key external interfaces, and an encapsulation mechanism that binds the adapter to the application and protects the combined components [BER99].

In this context, the software being protected contains the actual distributed objects, and the AICG model has no way of knowing the behaviors of the distributed object other than the type of operations of the methods. The adapter intercepts all invocations to provide additional functionalities such as synchronization between the local and distributed object, transaction control, events monitoring and exceptions handling. The encapsulation mechanism has been explained in the earlier section (AICG Architecture). Instead of instantiation of the actual object, the respective interface wrapper is instantiated. Instantiating the interface wrapper would indirectly instantiate the actual object as well as storing the object in the space.

Three classes are generated for every distributed object. These are named with the object name appended with the following Ext, ExtClient, and ExtServer. The class hierarchy of the example is shown in figure 16.

Figure 16, Wrapper Hierarchy

The trackExtClient class is initialized by applications that have only read access on the distributed object. Whereas, the trackExtServer class is initialized by applications that have both the read and write access on the distributed object. The listing of the three files are found in Appendix B.

## **C. EVENT MODULES**

The event modules consist of the event callback template (notifyAICG), the event handler (evenAICGHandler) and the event identification object (eventAICGID).

### **1. Event Identification Class**

The event identification class is used to distinguish one event from others. When an event of interest is registered, an event identification object is created by storing the identification and the event source. Together these two properties act to uniquely identify the event registration.

The class has only two methods, an 'equals' method that check if two event identification objects are the same and a 'to string' method which is used by the event handler for searching the right event objects from the hash table. The listing of the event identification class can be found in Appendix B.

### **2. Event Handler**

Event Handler is the main body of the event operations in the AICG model. It handles registration of new events, deletion of old events, listening for event and invoking the right callback for that event. In fact, the event handler consists of three inner classes to perform the above functions. Events are stored in a hash table with the event

identification object as the key to the hash table. This allows fast retriever of the event object and the respective callback methods.

The event handler listens for new events from the space or other sources. When an object is written to the space, an event is created by the space and captured by all the listeners. The event handler would immediately spawn a new thread and check whether the event is of interest to the application. Figure 17 shows the portion of the event handler that are executed when an event is received, the full listing of the module is found in Appendix B.

```
// call when an external event is "fired".
public void run() {
    // get the event id and source
    Object source = event.getSource();
    long id = event.getID();
    long seqN = event.getSequenceNumber();
    // create a new event identification object
    eventAICGID keyID= new eventAICGID(id,source);
    registerAICG tempReg;
    // create a key from the id and event source
    String key = new String(keyID.toString());
    // check if the key exist in the hash table (storage)
    if ((tempReg = (registerAICG) storage.get(key)) !=null)
    {
        // check if the event is an old or duplicate event
        if (seqN > tempReg.seqNum) {
            tempReg.seqNum = seqN;
            src.listenerAICGEvents(tempReg.anyObj);
        } else {
            // old events ignored
            return;
        }
    }
}
} // end of notifyHandler
} // end of class
```

Figure 17, Event Handler

### 3. The Callback Template

The callback template is a simple interface class with an abstract method `listenerAICGEvents`. Its main function is to allow the AICG model to invoke the application program when certain events of interest are "fired". As explained in section V.E, the template need to be implemented by the application that wishes to have notification. The interface abstract method need to be override by the application for the callback to work.

```
public interface notifyAICG
{
    // abstract method, to be override by the application
    // with the codes that are to execute when the event fired
    public abstract void listenerAICGEvents(Object obj);
}
```

Figure 18, notifyAICG interface

### D. THE TRANSACTION MODULES

The transaction modules consist of transaction interface (`transactionAICG`) and the transaction factory (`transactionManagerAICG`).

The transaction interface class comprise of a group of static methods that are used for obtaining reference to the transaction manager server anywhere on the network. It uses

the Java RMI registry or the look-up server to locate the transaction server.

The transaction factory uses the transaction interface to obtain the reference to the server, which is then used to create the default transaction or user-defined transaction. In short, the transaction factory performs the following:

1. Invoke the transaction interface to obtain a transaction manager.
2. Create default transaction with lease time of 5 seconds.
3. Create transactions with user define lease time.

#### **E. THE EXCEPTION MODULE**

The exception module defines all the exception codes that are returned to the application when certain unexpected conditions occur in the AICG model. The exception include:

- "NotDefinedExceptionCode"; unknown error occur.
- "SystemExceptionCode"; system level exceptions, such disk failure, network failure.
- "ObjectNotFoundException"; the space does not contain the object.
- "TransactionException"; transaction server not found, transaction expire before commit.

- "LeaseExpireException"; object lease has expired.
- "CommunicationException"; space communication errors.
- "UnusableObjectException"; object corrupted.
- "ObjectExistException"; there another object with the same key in the space.
- "NotificationException"; events notification errors.

## VII. CONCLUSIONS AND RECOMMENDATION

### A. CONCLUSIONS

This thesis demonstrates the ease of sharing distributed objects and automates the generation of generic interface wrappers directly from the Prototype System Description Languages. However, the design has a performance price penalty. Every read operation requires the interface to synchronize the local object with the distributed object before the value is returned. Every write operation requires two Space operations. Adding the overhead for transactions, event monitoring and control, reading operations are in the range of a hundred milliseconds and writing is in the range of a few hundred of milliseconds. The high overhead lies within the Java Virtual Machine (JVM), the JavaSpace Model and the network latency. Current versions of JVM and JavaSpace are in a premature state in terms of performance. Even so, the performances are still suitable for most applications that are not time critical. Similar implementations of distributed systems with the above features of AICG interface in CORBA and Java would not perform any better.

Performance is not the main concern regarding whether the AICG interface model is suitable for developing

interoperability between real-time applications, but predictability of the time and space of the operations are. Currently, the Java language lacks some important real-time programming features such as:

1. Language features for capturing common idioms for periodic activity and asynchronous event handling.
2. Predictability of time and space. The language must enable prediction of the worst-case execution time for language constructs, to avoid "priority inversion" and it should not run out of storage or fragment.

In the near future, if the JVM and the Java language embrace the Real-Time standards currently in final draft, it should be able to bridge the gap regarding requirements for real-time systems.

## **B. RECOMMENDATIONS**

The AICG model is now still in the premature stages to be a useful developer tool. More features and developments are needed before the model becomes indispensable for developing distributed applications. The following sections describe some of the features that would enhance the usefulness of the AICG model.

## **1. Graphical User Interface (GUI)**

A user-friendly Graphical Interface would allow users to develop applications using graphical objects to represent the interfaces and the distributed objects. The graphical editor would allow the developer to include operators, input and output similar to those of the CAPS system. An expert system would then provide the capability to generate the PSDL specifications for the graphical objects. This should speed up developments that use the AICG model.

## **2. Integration With The CAPS System**

AICG model's primary objective is to allow developer to improve their productivity in developing reliable distributed systems by simplifying the interoperability between them.

The current version of CAPS, on the other hand, allows developers to design and build reliable end-systems. Integration of the AICG model with CAPS would complement each other, resulting in a total solution for developing truly distributed systems.

## APPENDIX D. SETTING UP THE JAVASPACE ENVIRONMENT

EXTRACTED FROM THE NUTS AND BOLTS OF COMPILING AND RUNNING  
JAVASPACE PROGRAMS BY SUSANNE HUPFER

### Downloading the Software Packages

Compiling and running JavaSpaces programs requires the installation of three separate packages from Sun Microsystems--Java, Jini, and JavaSpaces software.

- If you don't already have the Java™ 2 SDK, Standard Edition, v 1.2.x installed on your machine, download it from Sun's Java 2 SDK  
<<http://www.java.sun.com/products/jdk/1.2/>>. The Jini and JavaSpaces software require version 1.2.x of the Java Development Kit, because they make use of RMI features that are not available in version 1.1 of the JDK.
- Next you'll need to download the Jini™ Technology Starter Kit, Version 1.0.1, from the Jini System Software 1.0 Product Offerings  
<<http://developer.java.sun.com/developer/products/jini/product.offerings.html>>. (Note that, as this article is being written, Version 1.0.1 is the latest release, and you'll therefore see the number "1.0.1" appearing in the commands; if there is a newer release when you read this article, you should substitute the newer version numbers as appropriate.) You'll have to click on the link "Register and accept the SCSL to access software downloads" and step through a free registration process in order to download the kit. The file you download is called `jini1_0_1.zip`. The Jini Technology Starter Kit contains Jini interfaces and classes, along with a number of services. It also contains the complete set of Sun Microsystems Jini specifications, documentation, and example code.
- Last, download the JavaSpaces™ Technology Kit (JSTK), Version 1.0.1, from the Jini System Software 1.0 Product Offerings  
<<http://developer.java.sun.com/developer/products/jini/product.offerings.html>>. Again, you'll need to click on the link "Register and accept the SCSL to access

software downloads." The file you download is called `jstk1_0_1.zip`; it contains the Sun Microsystems implementation of the JavaSpaces technology, along with documentation and example code.

## **Installing the Packages**

- Now that you've downloaded the three necessary software packages, you're ready to unpack and install them. First, if you don't already have Java™ 2 SDK™ version 1.2.x installed, follow the installation instructions that come with the package to install it on your platform. This article assumes that Java software is installed in `C:\jdk1.2.x\` on Windows platforms and `/jdk1.2.x/` on Solaris platforms.
- Next, you need to install the Jini Technology Starter Kit and then the JavaSpaces Technology Kit (JSTK). Note that the current packaging of the JSTK requires that the Jini software be installed first, because the software packages build upon one another; if this order is not followed, the installation and API documentation will not be correct. Here are the steps in the correct order:
  - Extract the files in `jini1_0_1.zip` to your chosen destination directory, using a ZIP extraction utility. For example, on the Windows platform, use a utility such as WinZip and specify that the software distribution should extract to a certain destination directory. If you specify `C:\` as the destination, you should now have a folder `C:\jini1_0_1` that contains the Jini files. On the Solaris platform, copy the file `jini1_0_1.zip` to a destination directory, `cd` to that directory, and then use a ZIP extraction program, for example `jar -xvf jini1_0_1.zip`. This document assumes that Jini software resides in `C:\jini1_0_1\` on Windows platforms and `/jini1_0_1/` on Solaris platforms.
  - Extract the files in `jstk1_0_1.zip` to the same destination directory. This results in some files being overwritten, so when asked whether you wish to replace any of the existing files, answer "yes".

## Configuring Your Machine Environment

Now that you have unpacked the software, you still need to do some configuration. The file `C:\jini1_0_1\index.html` (`/jini1_0_1/index.html` on Solaris) contains pointers to release notes and other documentation (much of which is found in the `doc` folder). You may want to read over the release notes for any information not covered in this document; in particular, the sections covering "Known Bugs" or "Known Issues" can be a useful starting point if you're experiencing a problem.

Make sure that the path to the basic tools provided by the Java Development Kit (for example, `java`, `javac`, and `appletviewer`) is specified in your executable path. For instance, on Windows platforms, you need to set the `PATH` environment variable as follows:

```
set PATH=%PATH%;C:\jdk1.2.x\bin;
```

As for your `CLASSPATH` environment variable, we recommend that you do not modify it. To run the standard run-time Jini services (see Starting the Required Run-time Services), no special classpath is needed. When you build and run your own JavaSpaces code, we recommend passing the required JAR files on the command line, rather than modifying the classpath or placing JAR files in the Java extensions directory (we'll explain further in Compiling JavaSpaces Programs).

## Starting the Required Run-time Services

JavaSpaces applications interact with one or more spaces, so to run a JavaSpaces application you'll need to have at least one JavaSpaces service running. But this itself depends on having a Jini infrastructure in place, and before you start a JavaSpaces service, you need to start these other run-time services:

- An **HTTP server**, which is used to download code to JavaSpaces clients.
- An **RMI Activation Daemon**, which takes care of managing the states of services, for instance restarting crashed services, or deactivating and reactivating services based on whether they're being used or not (these responsibilities are described in more detail below).

- A **Lookup Service**, which allows clients to look up and find the Jini services that are currently available on the local network.
- A **Transaction Manager**, which is needed if your JavaSpaces applications make use of transactions.

Once these services are up and running, you can start:

- A **JavaSpaces Service**.

When building and testing JavaSpaces applications, you'll most likely run these services and your JavaSpaces client programs on a single desktop machine, but when deploying your final code, you'll most likely run them in a multimachine environment. So, let's step through the details of starting each of these services, paying attention along the way to avoiding pitfalls that could occur as you move your code from testing into deployment.

### **Starting an HTTP Server**

Web servers are used for delivering class code to Jini clients. Let's take a brief look at how this works.

Whenever you run a JavaSpaces application that needs to serve classes to clients (for example, one that writes entries into a JavaSpace), you need to include "codebase" information on the command line (as you'll see in Running JavaSpaces Programs). The codebase specifies locations--usually URLs--from which a client can download the class files. Whenever your code writes entry objects into the space, the entries get annotated with that information. When a client of the space later removes or reads an entry object from the space, the entry's codebase annotation tells the client where to look for the class code, which is downloaded from an HTTP server (if the class doesn't already exist in the classpath). Typically you'll run a web server on each machine that needs to export code.

Any web server that's capable of serving documents can do the job, but for convenience, the Jini distribution provides a simple HTTP server in the tools.jar package. Here is the command to start the supplied HTTP server

(where optional parameters are shown in square brackets):

```
java -jar C:\jini1_0_1\lib\tools.jar
  [-port port-number]
  [-dir document-root-dir]
  [-verbose]
```

For example, on the Windows platform, you might issue this command:

```
java -jar C:\jini1_0_1\lib\tools.jar
  -port 8081
  -dir C:\jini1_0_1\lib
  -verbose
```

On Solaris, the equivalent command is:

```
java -jar /jini1_0_1/lib/tools.jar
  -port 8081
  -dir /jini1_0_1/lib
  -verbose
```

The JAR file containing the HTTP Server is C:\jini1\_0\_1\lib\tools.jar; this is an "executable JAR" file (introduced in the Java 2 platform), which means that it starts a default program (in this case, the HTTP server) when it's invoked as shown.

Here, you started the HTTP Server at port 8081 (if left unspecified, the port number would be 8080). The -dir option specifies which directory the server uses as its "document root." Here, you specified the Jini lib directory as the root, so this HTTP server is able to serve all the Jini JAR files in that directory (as well as other classes you might put there). The -verbose option causes information to be displayed about each request to the server, and is useful for debugging purposes.

### **Starting an RMI Activation Daemon**

An RMI Activation Daemon is needed by several other services--the Transaction Manager, the persistent JavaSpaces Service, and the Jini Lookup Service--and an instance of the daemon needs to be run on each of the machines where you run these services. What does an activation daemon do? Suppose you have a service that you'd like to be automatically restarted if it crashes (for instance, if the machine it is running on crashes). Or, suppose you're interested in conserving computational resources, so you'd like a service to be brought down when it has no active clients and

reactivated later when a client tries to use the service. An activation daemon takes care of restarting, deactivating, and reactivating your services (such as the Jini services mentioned above).

Let's see how to start an RMI activation daemon. First, be sure your executable path points to the bin directory of JDK1.2.2; this is where rmid is located. Again, make sure that you haven't modified your CLASSPATH environment variable or placed JAR files in the Java extensions directory.

Then, to start rmid under Windows or Solaris, the command takes the form:

```
rmid [-port port-number] [-log dir]
```

For example, to start the RMI Activation Daemon on either Windows or Solaris, you could use the command:

```
rmid
```

to start the daemon on the default port of 1098. For further information on starting rmid, refer to the manual pages for Solaris

<<http://java.sun.com/products/jdk/1.2/docs/tooldocs/solaris/rmid.html>>

or Windows

<<http://java.sun.com/products/jdk/1.2/docs/tooldocs/win32/rmid.html>>.

## Starting a Lookup Service

A lookup service registers the Jini services available on the local network, and is used by applications to locate services such as a JavaSpace. You can currently choose to use either the RMI registry or the Jini lookup service to serve this purpose, but you should be aware that future versions of Jini services may not support the use of the RMI registry. Therefore, this document only covers using the Jini lookup service (if you really want to use the RMI registry, you can find the details in c:\jini1\_0\_1\doc\example\StartingService.html).

The command to start the Jini lookup service takes this form:

```
java -Djava.security.policy=security-policy-file
```

```
-jar C:\jini1_0_1\lib\reggie.jar  
lookup-codebase  
security-policy-file  
log-directory  
[lookup-group]
```

Let's examine each of the parameters.

The `-Djava.security.policy` option to `java` specifies a "security policy file" for the JVM to use when it runs the lookup service JAR file. The concept of a security policy file is new in the Java 2 platform; it is used to specify what resources a program can use when it runs--for example, whether it is permitted to access system properties, create and listen to socket connections, write to log files, and so on--and what level of privileges to grant to any downloaded code.

The JAR file containing Sun's implementation of the lookup service (called "reggie") is `C:\jini1_0_1\lib\reggie.jar`. Once again, this is an executable JAR file, which means it will start running (in a "setup JVM") when it's invoked as shown. First the remaining parameters are parsed, then the reggie lookup service is registered with the RMI Activation Daemon you started earlier on the same machine, and then the setup JVM exits (don't be alarmed that your command returns at this point, and that your DOS window, under Windows, says "Finished"). The lookup service is activatable: It will be restarted automatically by the activation daemon after crashes, and it will shift between "active" and "inactive" states as appropriate. In this case, the activation daemon spawns a new "server JVM" to run the lookup service; in fact, whenever a lookup service is activated, a new "server JVM" is spawned to run that instance of the service.

The final four parameters deserve a closer look. The `lookup-codebase` option specifies a URL that points to the `reggie-dl.jar` file, which contains the code that clients need to download to use the lookup service. For example, you might specify a URL to the HTTP server you started earlier, that is, `http://hostname:port/reggie-dl.jar`, where `hostname` is the name or IP address of the machine on which the HTTP server is running, and `port` is the port number at which it is running. You also need to ensure that the specified HTTP server can access `reggie-dl.jar` under its document root directory. To test to make sure the JAR file is accessible, you

can try accessing it from a browser, using the codebase URL. Since you started the web server in verbose mode, you should see a request logged to its screen, and you'll most likely see a "Save To" dialog box (unless the browser has been configured to handle .jar files).

The next option, *lookup-policy-file*, specifies another security policy file. The first security policy file you specified is used only by the setup JVM, while this second (potentially different) security policy file is used by the server JVM whenever the lookup service is reactivated.

The next parameter, *log-directory*, specifies an absolute path name to a directory (on the file system where the lookup service is running) where the lookup service writes its logs. It's important to point out that this directory should not already exist, or the setup JVM will exit without registering the lookup service.

The final, optional parameter, *lookup-group*, is used to specify a "group" of services for which reggie provides lookup service. Usually, you use the special group name *public*, which Jini services conventionally join; if you omit the parameter, the default is *public*.

Here is an example command for starting the reggie lookup service on Windows:

```
java -Djava.security.policy=C:\jini1_0_1\example\lookup\policy.all
-jar C:\jini1_0_1\lib\reggie.jar
http://hostname:8081/reggie-dl.jar
C:\jini1_0_1\example\lookup\policy.all
C:\tmp\reggie_log
public
```

where *hostname* is the name or IP address of the machine on which the HTTP server is running.

Here is what the example command looks like on the Solaris platform:

```
java -Djava.security.policy=/jini1_0_1/example/lookup/policy.all
-jar /jini1_0_1/lib/reggie.jar
http://hostname:8081/reggie-dl.jar
/jini1_0_1/example/lookup/policy.all
/tmp/reggie_log
public
```

You should note that using the *policy.all* file as shown is fine when you're experimenting with your code, but it's not recommended for production use, since it grants all permissions to all code (trusted or not).

When deploying your code in a production environment, make sure you've devised careful policies that restrict access appropriately (for instance, your policy might state that downloaded code cannot access certain parts of your file system). The topic of security in the Java 2 platform is beyond the scope of this article.

## Starting a Transaction Manager

If your JavaSpaces applications make use of transactions, you'll need to start a transaction manager service next, with a command of the form:

```
java -Djava.security.policy=security-policy-file
      -Dcom.sun.jini.mahalo.managerName=txnmanager-name
      -jar C:\jini1_0_1\lib\mahalo.jar
      txnmanager-codebase
      security-policy-file
      log-directory
      [lookup-group]
```

(Note that, if you're using an RMI registry instead of the Jini Lookup, you'll need to modify the command slightly; refer to C:\jini1\_0\_1\doc\example\StartingService.html.)

The executable JAR file containing Sun's implementation of the Transaction Manager Service (called "mahalo") is C:\jini1\_0\_1\lib\mahalo.jar. Like the lookup service, the transaction manager service is activatable: When the command above is run, a "setup JVM" registers the transaction manager with the RMI activation daemon--which activates the manager in a newly spawned "server JVM"--and then exits. Once again, the command line returns once the registration is complete, and you should see a command prompt.

The *security-policy-file* options mean what you would expect, given our previous discussion about starting the Jini Lookup Service: The *-Djava.security.policy* option governs the permissions the setup JVM uses, while the second *security-policy-file* option specifies the permissions that the server JVM uses whenever the Transaction Manager Service is activated.

The option *-Dcom.sun.jini.mahalo.managerName* allows you to specify a name (such as "TransactionManager") for the transaction manager if you wish: this name becomes an attribute attached to the transaction manager in the

lookup service, and can be used to look up this particular transaction service later on.

Just as you did with the lookup service, you need to supply a codebase option to the service, specifying a URL to the mahalo-dl.jar file, which contains the code that clients need to download to use the transaction manager service. For example, you might supply a URL pointing to the hostname and port number of the HTTP server you started earlier. Be sure that the specified HTTP server can access mahalo-dl.jar under its root directory. Once again, you may want to try accessing the JAR file using a web browser and your codebase URL, to make sure the file is accessible.

The next parameter, *log-directory*, should specify an absolute path name to a directory (on the file system where the Transaction Manager service is running) where the service writes its logs. You should make sure that the log file doesn't already exist.

For the last (optional) parameter, you can specify the name of a Jini group for the Transaction Manager to join; for example, *public* means the manager should become part of the public group.

Here's an example of starting a Transaction Manager, using the Jini Lookup service, on Windows:

```
java -Djava.security.policy=C:\jini1_0_1\example\txn\policy.all
-jar C:\jini1_0_1\lib\mahalo.jar
http://hostname:8081/mahalo-dl.jar
C:\jini1_0_1\example\txn\policy.all
C:\tmp\txn_log
public
```

where again, *hostname* is the name or IP address of the machine on which the HTTP server is running. On Solaris, the command looks like this:

```
java -Djava.security.policy=/jini1_0_1/example/txn/policy.all
-jar /jini1_0_1/lib/mahalo.jar
http://hostname:8081/mahalo-dl.jar
/jini1_0_1/example/txn/policy.all
/tmp/txn_log
public
```

## Starting a JavaSpaces Service

Now that you've started all the supporting services (HTTP Server, RMI Activation Daemon, Jini Lookup

Service, and Transaction Manager Service), you can finally start a JavaSpaces service (Sun's implementation is known as "outrigger"). You can choose to start either a JavaSpaces service called TransientSpace (one that doesn't maintain data across crashes and restarts of the space) or a persistent JavaSpaces service called FrontEndSpace (one that does maintain data across crashes and restarts).

### Starting a Transient JavaSpace

To start a TransientSpace JavaSpaces service, given that you're running a Jini Lookup Service, the command takes the following form:

```
java -Djava.security.policy=security-policy-file
      -Djava.rmi.server.codebase=javaspace-codebase
      -Dcom.sun.jini.outrigger.spaceName=space-name
      -jar C:\jini1_0_1\lib\transient-outrigger.jar
      [lookup-group]
```

(Refer to C:\jini1\_0\_1\doc\example\StartingService.html for the details of formatting the command if you're using an RMI registry instead.)

Let's examine the parameters. The *security-policy-file* option governs the permissions the JVM uses when running the JavaSpaces service. The *javaspace-codebase* option specifies a URL that points to the *outrigger-dl.jar* code that clients must download in order to use the JavaSpaces service. The *Dcom.sun.jini.outrigger.spaceName* option is used to specify a name for the JavaSpaces service (for example, "JavaSpaces"). And as you saw with the transaction manager service, you can optionally specify the name of a Jini community for this service to join.

It's worth noting here that a transient JavaSpace service is not an activatable service, and the command above is handled by just a single JVM. This is why you don't need to pass additional arguments (*codebase*, *security-policy-file*, *log-directory*) at the end of the command as you did for the lookup service and transaction manager service. The JVM that executes the command will continue to run until the JavaSpaces service exits or gets killed, so unlike the activatable services, you will not be returned to the command prompt while the space is running.

Here's an example of starting a transient JavaSpace, using the Jini Lookup service, on Windows:

```
java -Djava.security.policy=C:\jini1_0_1\example\books\policy.all
-Djava.rmi.server.codebase=http://hostname:8081/outrigger-dl.jar
-Dcom.sun.jini.outrigger.spaceName=JavaSpaces
-jar C:\jini1_0_1\lib\transient-outrigger.jar
public
```

On the Solaris platform, the equivalent command looks like this:

```
java -Djava.security.policy=/jini1_0_1/example/books/policy.all
-Djava.rmi.server.codebase=http://hostname:8081/outrigger-dl.jar
-Dcom.sun.jini.outrigger.spaceName=JavaSpaces
-jar /jini1_0_1/lib/transient-outrigger.jar
public
```

Again, you should note that the policy.all file is fine for your code experimentation, but you should revisit the security policy issue when you deploy your code in a production environment.

### **Starting a Persistent Javaspaces**

In a deployment environment, you're likely going to want to run a persistent FrontEndSpace JavaSpaces service rather than a transient JavaSpaces service. A FrontEndSpace is able to maintain its data, even through crashes and restarts of the space.

To start a FrontEndSpace JavaSpaces service, given that you're running a Jini Lookup Service, the command takes the following form:

```
java -Djava.security.policy=security-policy-file
-Dcom.sun.jini.outrigger.spaceName=space-name
-jar C:\jini1_0_1\lib\outrigger.jar
javaspace-codebase
security-policy-file
log-directory
[lookup-group]
```

Since FrontEndSpace is an activatable JavaSpaces service, you'll notice some differences from starting a transient space. First, the codebase is specified differently. Second, you must supply a second security policy file (as you did when starting the lookup service and the transaction manager, to be used when the service is reactivated by the RMI Activation Daemon). Last, you must supply an absolute path name to a directory where the JavaSpaces service writes log files.

Note that outrigger.jar contains all the classes needed for the JavaSpaces service to run a FrontEndSpace. Here's an example of starting a FrontEndSpace, using a Jini Lookup service, on the Windows platform:

```
java -Djava.security.policy=C:\jini1_0_1\example\books\policy.all
-jar C:\jini1_0_1\lib\outrigger.jar
http://hostname:8081/outrigger-dl.jar
-Dcom.sun.jini.outrigger.spaceName=JavaSpaces
C:\jini1_0_1\example\books\policy.all
C:\tmp\js_log
public
```

Here's an example of starting a FrontEndSpace on Solaris:

```
java -Djava.security.policy=/jini1_0_1/example/books/policy.all
-jar /jini1_0_1/lib/outrigger.jar
http://hostname:8081/outrigger-dl.jar
-Dcom.sun.jini.outrigger.spaceName=JavaSpaces
/jini1_0_1/example/books/policy.all
/tmp/js_log
public
```

As you saw with other activatable services, issuing these commands returns a command prompt.

## Compiling JavaSpaces Programs

By now, you have all the required Jini services up and running. Assuming you've already written a JavaSpaces client program (one that makes use of a JavaSpaces service), all that's left is to compile your code and run it.

If you wish, you can experiment with a very simple "Hello World" program from *JavaSpaces Principles, Patterns and Practice*. You need to edit the compile.bat file and replace localhost:8081 with the IP address and port number of your web server, and then you can simply run compile.bat and runit.bat to get the example up and running under Windows.

When compiling JavaSpaces programs, the javac compiler (and later the java bytecode interpreter) may need access to several different jar files:

- jini-core.jar, which contains the core Jini interfaces and classes and is needed whenever your program makes use of leases or events, for example.
- jini-ext.jar, which contains additional interfaces that are useful in building Jini applications, including the JavaSpaces interface.

- sun-util.jar, which contains a set of useful helper utilities. These classes may change, however, since they are regarded as non-standard.
- space-examples.jar, which contains various JavaSpaces technology examples and includes the classes com.sun.jini.mahout Locator, com.sun.jini.outtrigger.LookupFinder, and com.sun.jini.outtrigger.Finder, which are needed when compiling the SpaceAccessor.java code found in Chapter 1 of the *JavaSpaces™ Principles, Patterns and Practice* <<http://www.amazon.com/exec/obidos/ASIN/0201309556/>>.

When compiling your JavaSpaces programs, supply a -classpath option to the javac compiler. For example, to compile ExampleProgram.java on Windows, the command might look like this:

```
javac -d . -classpath
C:\jini1_0_1\lib\jini-core.jar;
C:\jini1_0_1\lib\jini-ext.jar;
C:\jini1_0_1\lib\sun-util.jar;
C:\jini1_0_1\lib\space-examples.jar;.;
ExampleProgram.java
```

Note that these JAR files might not all be necessary for every compilation; it depends on the specifics of the program you're compiling. Also note the use of the -d option; here it is used to specify that class files should be created in the current directory. The .; appearing at the end of the classpath option indicates that the current directory is searched for classes, along with the JAR files listed. You should tailor these options according to where you want your class files stored.

On Solaris, the equivalent command looks like this:

```
javac -d . -classpath
/jini1_0_1/lib/jini-core.jar:
/jini1_0_1/lib/jini-ext.jar:
/jini1_0_1/lib/sun-util.jar:
/jini1_0_1/lib/space-examples.jar::
ExampleProgram.java
```

Alternately, you could specify the required JAR files in the CLASSPATH environment variable or place JAR files in the Java extensions folder. However, during the code development phase--when you're likely running a JavaSpaces service and client programs on the same machine--avoiding these modifications to the classpath environment is a good policy: It helps to avoid unintended sharing of class files, and to simulate a deployment environment--when Jini services, such as a JavaSpace, and client programs that make use of them

are likely to run on different machines. Avoiding use of the CLASSPATH and Java extensions can help to reduce the problems you'll encounter when you move from development to deployment.

## Running JavaSpaces Programs

Now that you've compiled your JavaSpaces programs, you're ready to run them. Assuming you're running the Jini Lookup service on the Windows platform, the command takes this form:

```
java -Djava.security.policy=C:\jini1_0_1\example\books\policy.all
-Doutrigger.spacename=JavaSpaces
-Dcom.sun.jini.lookup.groups=public
-cp C:\jini1_0_1\lib\space-examples.jar;
    C:\jini1_0_1\lib\jini-core.jar;
    C:\jini1_0_1\lib\jini-ext.jar;
-Djava.rmi.server.codebase=http://hostname:8081/space-examples-dl.jar
ExampleProgram
```

On Solaris, the command takes this form:

```
java -Djava.security.policy=/jini1_0_1/example/books/policy.all
-Doutrigger.spacename=JavaSpaces
-Dcom.sun.jini.lookup.groups=public
-cp /jini1_0_1/lib/space-examples.jar;
    /jini1_0_1/lib/jini-core.jar;
    /jini1_0_1/lib/jini-ext.jar;
-Djava.rmi.server.codebase=http://hostname:8081/space-examples-dl.jar
ExampleProgram
```

Let's take a look at each of the parameters. The `-Djava.security.policy` option specifies the path to the security policy file you'd like your program to use when it runs downloaded code (for example, if your program retrieves an entry from a JavaSpace and invokes one of its methods). If you find none of the policy files provided in the Jini distribution to be suitable, you'll have to modify one to meet your needs.

With the `-Doutrigger.spacename` option, you can specify the name of the specific JavaSpaces service you'd like your program to use (with the command above, you're specifying that your program should interact with a space called "JavaSpaces", if one can be found, not one called "Old JavaSpace" or anything else).

The `-Dcom.sun.jini.lookup.groups` option specifies which Jini community this program runs under (here, the public group).

The Java bytecode interpreter (java) needs access to several JAR files; the exact ones depend on what your program does. Refer to the list of JAR files in Compiling JavaSpaces Programs.

The codebase property needs to be set if your program is exporting downloadable code, for instance if your program is writing entries into a JavaSpace. In this case, when other programs read or remove those entries, they need to know where they can download the classes for those entries. This information is provided by your program, which annotates the entries it writes into the space with information from the codebase property. The codebase property also needs to be set if your program is requesting notification services from any of the Jini services; in this case the "listener" code needs to be exported.
